SUMMARY

The Biloela Research Station is situated in the Callide Valley of central Queensland, approximately 100 km south-west of Gladstone. Current research on the 240 ha station includes plant breeding, crop variety testing, crop nutritional work, weed control research and soil management studies.

The boundaries enclose part of an extensive alluvial plain and a small area of gently undulating rises. The rises have developed on Tertiary sedimentary rocks while subsequent Quaternary deposition has resulted in an alluvial plain covering the lower landscape positions.

A very high intensity grid survey (scale 1:5 000) was undertaken to identify and map the soils present. Six soil types, including one gravelly phase, were identified and are described in detail. A grey and brown massive earth, a dark non-cracking clay to duplex soil and a black earth occur on the levees transecting the alluvial plain. Another black earth and two dark non-cracking clays occupy the intervening flats and drainage depressions. A number of very shallow and stony, miscellaneous soils were also delineated on the gently undulating rises. Soil distribution is shown on the accompanying map.

The soils of the alluvial plain are non-saline and non-sodic. They have similar levels of plant nutrients in the surface soil with only organic carbon and total nitrogen reserves being low. Levels of exchangeable cations are adequate throughout all profiles and the soil cation exchange capacities are also considered adequate to retain these nutrients against leaching.

The soil physical characteristics are more variable. Particle size analysis reveals two distinct groups with one having less clay and silt and more fine sand than the other. The condition of the surface soil and subsoil structure also vary. Three groups can be identified on the basis of plant available water capacity but different groups are obtained when considering deep drainage characteristics.

The implications for designing field trials are discussed.

1. INTRODUCTION

1.1 Location and history

The Biloela Research Station is situated in the Callide Valley of central Queensland, approximately 100 km south-west of Gladstone (Figure 1).

The station was established in 1924 as the Callide Cotton Research Station. It was initially developed as a demonstration farm to show new settlers appropriate cotton management practices for the soils of the Callide alluvium. This initial role soon expanded into an investigation of all potential crops for the area (McTaggart 1987).

The station now comprises 240 ha of which 150 ha can be irrigated from shallow aquifers. The current research programme includes:

- . Cotton and sorghum plant breeding;
- . Summer and winter crop variety testing;
- . Crop nutritional work;
- . Weed control research;
- . Soil management studies;
- . Insect research;
- . Pig research; and
- . Agricultural engineering development.

1.2 Aims of the survey

The aims of this survey were to describe and map the soils of the research station and to comment on their homogeneity for experimentation. Previously published soils data are of insufficient detail for this purpose. A comprehensive soils report also allows more precise comparison of the soils with those of the surrounding district serviced by the station.

2. CLIMATE

Rainfall is the major climatic element determining plant growth. The mean annual rainfall recorded for the 60 year period 1924 to 1984 at Biloela Research Station is 699 mm. Mean monthly values are presented in Table 1.

Table 1. Mean rainfall, mean pan evaporation and 9 am relative humidityfor Biloela Research Station

	J	F	M	A	M	J	J	A	S	0	N	D	Annual

Source: Bureau of Meteorology

Annual totals are highly variable, due to the convective origin of much of the rainfall and the sporadic incidence of rainfall depressions associated with tropical cyclones. This is evident in Figure 2 which shows the rainfall values equalled or exceeded in one in ten years, five in ten years (median) and nine in ten years.

Figure 2 also demonstrates a marked seasonal distribution. Median rainfall for the six warmer months, October to March, represents 69% of the median value for the entire 12 month period beginning in October.

The EI₃₀ rainfall erosion index has been calculated for the research station by Rosenthal and White (1980). The index is a function of total storm energy and the maximum 30 minute rainfall intensity of the storm. The average annual EI₃₀ and the average monthly figures, expressed as a percentage of the annual index, are given in Table 2. Compared with similar agricultural centres further south the annual value is lower than for Kingaroy (EI₃₀ of 283) but higher than both Dalby (174) and Inverell (200).

Table 2.Average annual erosion index (EI30) and average monthly indexfor Biloela Research Station

Figure 1

Temperature data are given in Table 3 for the research station. Between October and March an average 26 days experience maximum temperatures of at least 35oC but very few days are likely to reach 38oC. Skerman (1958) showed that heat waves (three consecutive days with temperatures over 37.8oC) adversely affect grain sorghum. The probability of heat waves occurring at Biloela is remote. An average 21 days have minimum temperatures of less than 2oC between May and September. At screen temperatures of 2oC, light frosts can be expected. The eight days with minimum temperatures less than 0oC represent the average number of heavy frosts which occur.

Relative humidity and pan evaporation data are presented in Table 1. The mean monthly pan evaporation exceeds mean rainfall in all months.

3. GEOLOGY AND LANDFORM

3.1 Geology

The geology of the Callide Valley has been described by Dear *et al.* (1971). The valley may have formed as a result of fault movements during the Tertiary period (65 to 1.8 million years before present).

A thick sequence of flat-lying sediments was deposited during this period. The office and glasshouse complex are situated on this sequence. The sedimentary rocks are soft and consist mostly of grey clay shale and white to buff quartz sandstone. Minor pebble conglomerate and thin coal seams have also been reported.

Subsequent fluvial action resulted in deposits of clay, sand and gravel forming an extensive alluvial plain across the lower parts of the landscape. The research station is mainly sited on these Quaternary sediments (1.8 million years to present). Their maximum thickness is approximately 25 m.

3.2 Landform

The flat-lying Tertiary rocks form gently undulating rises with predominantly 2 to 3% slopes. Elevation varies between approximately 180 and 190 m. The Washpool Gully forms their northern border and also marks the southern limit of the alluvial plain.

The alluvial plain has an elevation of approximately 170 m. Callide Creek dissects the plain and forms the northern boundary of the research station. Between Callide Creek and the Washpool Gully are a series of levees separated occasionally by intervening flats. One flat contains a lower lying, run-on area most appropriately described as a backplain. Several open drainage depressions also transect the area.

Three of the drainage depressions have the position, direction, shape and deep incision similar to stream channels. They appear to be former courses, either main channels or overflow channels, of Callide Creek.

4. HYDROLOGY

The research station is drained by Callide Creek and, to a lesser extent, Washpool Gully. Queensland Water Resources Commission records indicate that Callide Creek has overtopped its banks only twice at Biloela since the station was established. The Washpool Gully has not caused flooding on the station.

Underground water resources are available in the recent (Quaternary) alluvial deposits which overlie the Tertiary sedimentary rocks. Their most important aquifer consists of clean gravel and sand and attains a maximum thickness of 9 m (Dear *et al.* 1971).

The standing water level varies between 8 and 12 m below ground level. Water quality is indicated for four bores in Table 4. Gill (1984) developed a scheme for classifying the quality of water for irrigation in Queensland. According to this scheme, all four bores have water suitable for irrigating all crops except tobacco, and they have no sodium problem.

Measurement	Unit	Bore number

5. VEGETATION

Speck (1968) has described the vegetation of the Callide Valley. The research station has been extensively cleared and only remnants of the native vegetation occur.

Scattered trees of brigalow (Acacia harpophylla) and narrow leaf bottle tree (Brachychiton rupestris) remain on the gently undulating rises as well as isolated clumps of narrow leaved ironbark (Eucalyptus crebra), variable bark bloodwood (E. erythrophloia) and Moreton Bay ash (E. tessellaris).

The levees of the alluvial plain contain isolated trees of Queensland blue gum (E. tereticornis), Moreton Bay ash, silver leaved ironbark (E. melanophloia) and sally wattle (A. salicina).

The vegetation fringing Callide Creek and the Washpool Gully includes Queensland blue gum, Moreton Bay ash, silver leaved ironbark, sally wattle, long fruited bloodwood (E. polycarpa), snow-in-summer (Melaleuca linariifolia), black teatree (M. bracteata), river sheoak (Casuarina cunninghamii), weeping bottle brush (Callistemon viminalis) and bauhinia (Lysiphyllum hookeri). Minor softwood species such as figs (Ficus spp.), white cedar (Melia azederach) and boonaree (Heterodendrum oleifolium) also occur on Callide Creek.

6. SOIL SURVEY METHOD

The scale of published soil maps should be determined by the purpose of the survey (McDonald 1975). The density of ground observations should then be appropriate for the selected scale. Biloela Research Station is used for small plot experiments such as plant breeding, crop variety testing and weed control research. A very high intensity mapping scale (1:10 000 or larger) was therefore chosen for the alluvial plain where experimentation is carried out.

Ground observations were recorded every 100 m along fixed traverses set 100 m apart. The distance between observations was varied where necessary to avoid highly disturbed sites. Sites were described according to McDonald *et al.*(1984). Soil profiles were described to a depth of 1.5 m or gravel, whichever occurred first.

The site descriptions were sorted into three landscape units and six soil types (see section 7.2). The six soils were then mapped on air photos (scale 1:5 000). Additional ground observations were taken to verify map boundaries. A total of 199 ground observations were recorded on the alluvial plain at a frequency of one per 1.1 ha.

Only two sites were described on the gently undulating rises giving an approximate density of one per 6 ha. Field plot experimentation is not carried out on this area.

7. SOILS - MORPHOLOGY, CLASSIFICATION AND DISTRIBUTION

7.1 Previously published soils data

Isbell (1954) prepared a reconnaissance soil map of the Callide Valley at a scale of approximately 1:250 000. Soil associations were also delineated by landscapes as part of the Atlas of Australian Soils (Isbell *et al.* 1967). Mapping scale was 1:2 000 000. Sweeney (1968) identified soil families of the Dawson-Fitzroy area but did not delineate them on a map.

7.2 Definition and description of soil types

Six soil types, a soil phase and one group of miscellaneous soils were identified.

A soil type is a three-dimensional soil body. Any profile within this body has a similar number and arrangement of major horizons whose attributes, primarily morphological, are within a defined range. All profiles within the soil type have similar parent materials. A soil phase is a subdivision of the soil type based on attributes which have notable significance in the use of the soil (R.C. McDonald, personal communication).

A few soils were not adequately described and named as soil types because of their negligible agricultural value and extent. They are referred to as miscellaneous soils.

A detailed description and classification of the soil types are given in Table 5. The conventions used in Table 5 are explained in Appendix 1.

7.3 Relationship between soils

The soils have been arranged into three landscape units on the basis of landform and parent material.

7.3.1 Soils of the very gently to gently undulating levees

Hodge, Callide and Woodall soil types occur on the levees transecting the alluvial plain. Hodge is situated adjacent to Callide Creek, Woodall occurs in close proximity to the Washpool Gully and Callide occupies the levees in between. All three have a neutral to alkaline soil reaction trend and overlie similar buried layers (D horizons). Profile development appears to increase with distance from Callide Creek.

Hodge is a dark, grey or brown gradational soil with hard setting sandy clay loam to clay loam, sandy surface soil (A horizons) and massive to moderately pedal sandy clay subsoil (B horizons) and medium sized sand grains (Northcote 1979, p.26) are evident throughout the profile.

Callide is a dark, gradational soil, duplex soil or non-cracking clay. The sandy clay loam to light medium clay surface soil either hardsets or crusts; the light medium clay to heavy clay subsoil is moderately pedal and medium to fine sand occurs throughout the profile.

Table 5.	Detailed	description	and	classification	of	the soils

	Uf 6.42P	65-85	300 B21	Ap or A1 - dark to grey-brown (5 YR, 7.5 YR 2/1, 2/2, 3/1, 3/2, 4/1, 4/2), grey-brown (dry), sandy clay loam to fine sandy, light medium clay; massive to weak 2 to 5 mm subangular blocky; dry moderately firm		irondark and sally wattle trees
		7087	600	to moderately strong; abrupt to gradual to - B1 (where present) - dark to grey-brown (5 YR, 7.5 YR		
		7087	900	2/1, 3/1, 4/2), may have few fine distinct brown mottles, sandy clay to fine sandy, light medium clay; dry very firm, clear to gradual to -		
		80-90	1200 D s	B21 - dark to grey-brown (5 YR, 7.5 YR 2/1, 2/2, 3/1, 3/2, 4/1, 4/2), may have many fine to medium distinct brown mottles; sandy, light medium clay to fine sandy, heavy clay; moderately moist very firm to moderately strong; may have few subrounded fine gravels; clear to diffuse to -		
		80-90	1500 \	B22? (where present) - mottled dark to grey-brown and yellow-brown to red-brown (5 YR, 7.5 YR 2/1, 3/1, 3/2, 4/1, 4/2 and 3/3, 4/3, 4/4, 5/4, 5/3); fine sandy, light medium clay to sandy, heavy clay; dry very firm to very strong; may have few subrounded fine gravels; may have few fine to coarse nodular and soft carbonate; clear to diffuse to -		
				D's (where present) - either whole coloured or mottled, red-brown to yellow-brown or grey brown to dark (5 YR, 7.5 YR 4/3, 4/4, 5/3, 5/4, 5/6, 3/1, 3/2, 4/1, 4/2); coarse sand to sandy, medium clay or light medium clay to heavy clay; may have few subrounded fine to medium gravels; may have many fine to coarse soft and nodular carbonate		
				<u>Comments</u> : Fine sand or sand is present in the Ap or A1 horizon and is common in the B21 and B22? horizons. The B22? horizon appears to form a transition layer from the B21 to the D horizons. The D horizons are recognised by either substantial decrease in texture, often associated with a change in the size of sand present, or by a change to clay layers with no sand present at all.		
				<u>Phase</u> : A gravelly phase, with very few to many subrounded fine to medium gravels in the A, B1, B2 horizons and with few to very abundant subrounded fine to medium gravels in the D horizons, occurs in the north-east of the study area.

Woodall is a dark, cracking clay with self-mulching light medium to medium heavy clay surface soil overlying moderately pedal medium clay to heavy clay subsoil with fine sand evident in the surface soil of some profiles.

A Callide gravelly phase occurs in the north east-corner of the station (blocks V to Z). The phase has a few to very abundant subrounded gravels present in some part of all profiles compared with none to few gravels occasionally present in Callide profiles. Spatial distribution is not consistent and the two cannot be mapped separately.

7.3.2 Soils of the intervening level flats and drainage depressions

Level alluvial flats occasionally separate the levees containing **Callide** soil. A dark, non-cracking clay, **Melton**, occurs on these flats. Both **Melton** and **Callide** have neutral to alkaline soil reaction trend and overlie similar buried layers. **Melton** has a heavier texture in the surface soil (light medium to medium heavy clay) and subsoil (medium clay to heavy clay). In contrast with **Callide**, sand is present only in the surface soil of **Melton** where adjacent to levee footslopes.

Shallow open drainage depressions occur within the alluvial flats and between the Woodall levees. These depressions contain Tognolini soil. Tognolini is a dark clay, generally cracking but occasionally non-cracking. Melton and Tognolini have similar textures, neutral to alkaline soil reaction trend and overlie similar buried layers. In contrast with Melton, the Tognolini surface soil is self-mulching and seasonal cracking generally occurs. Woodall and Tognolini have similar morphological properties but have been distinguished due to landform position. Tognolini also occupies the area of backplain.

Three deeper drainage depressions have Channel soil. Channel is a dark, non-cracking clay with neutral to alkaline soil reaction trend. Its features include a surface crust when dry and fine to medium sand often evident through the profile, distinguishing this soil from Melton.

7.3.3 Soils of the gently undulating rises

Very shallow (<0.5 m depth) and stony, unnamed, miscellaneous soils occupy these uplands. They are mainly non-cracking clays with dark surface soil and brown subsoil. Soil reaction trend is acid to neutral.

7.4 Soil correlation with previous data

The soils data available to date were published between 1954 and 1968. Since 1981, extensive land planing and drainage works have been implemented to facilitate flood irrigation. The surface soil has probably been substantially modified during this period and it is unlikely that soil profile descriptions taken during this survey entirely match those taken previously.

The previous surveys were of very low intensity aimed at broad regional assessment whereas this is a very high intensity survey. Nevertheless, some approximate correlations are given in Table 6.

Soil type	Soil family (Sweeney 1968)	Soil gr oup (Isbell 1954)	Soil association - landscape Isbell <i>et al</i> . (1967)
Hodge Callide Woodall	Warrinilla) Warrinilla, Retro) (a)) Rotro?)) Alluwial soils)	
Tognolini Channel	Vermont) (a))	Alluvial solls))	<u>n(</u> ; 4

 Table 6. Approximate correlation of soil types with previously published soils data

(a) There is no equivalent for these soils.

Both Sweeney (1968) and Isbell *et al.*(1967) indicate that the dominant soils on the alluvial plain are dark duplex soils. Sweeney (1968) describes them as having thin surface soils, generally 0.10 to 0.15 m thick. It is possible that the considerable ploughing and land planing has converted these soils into dark, uniform non-cracking clays.

7.5 Mapping units

Mapping units are areas of land with a consistent combination of soil types (after Beckett and Webster 1971). Each mapping unit is named after the dominant soil type present.

Any area that consists of a variety of soils with too few descriptions of each to adequately describe soil types is referred to as miscellaneous soils. This term is used to describe the soils of the gently undulating rises.

The enclosed soils map shows the distribution of the mapping units and Table 7 lists the soils that occur in them.

8. SOILS - CHEMICAL AND PHYSICAL ATTRIBUTES

8.1 Introduction

Ten soil profiles were sampled for detailed laboratory characterisation. These profiles represent the six soil types and one soil phase identified on the station. Location of the ten sampling sites are shown on the enclosed soils map.

All profiles were sampled with a jarret auger in 100 mm increments to a depth of 1500 mm. A bulk 0-100 mm surface sample (composite of 10 subsamples) was also collected for surface fertility assessment. Details of laboratory analyses performed on all samples are outlined in Table 8. The specific analytical methods together with some general data interpretations are listed in Bruce and Rayment (1982).

A correlation matrix was established to initially scan the data for significant relationships between some measured and derived attributes. Simple linear regression equations were calculated for some of the significant correlations. Analysis of variance was used to test for soil differences in total phosphorus and total potassium at each sampling depth; soil means were compared using the protected LSD test.

Detailed morphological and laboratory data for the 10 soil profiles are given in Appendix II.

Table 8. Laboratory analyses performed on the soil samples

(a) All analyses described in Bruce and Rayment (1982)

(b) These analyses also performed on all intermediate depths to 1500 mm

8.2 pH and salinity

Surface pH (0-100 mm) ranges from 6.9 to 7.6 but pH increases in all profiles becoming moderately to strongly alkaline at depth. This alkaline reaction trend is represented by the regression equation:

 $pH = 7.1 + .001 Depth (n = 150, r^2 = .72, P<.01)$

where pH is measured on a 1:5 suspension and depth is expressed in millimetres. At 900 mm the pH varies from 7.9 to 8.5 and at 1500 mm the range is 8.1 to 8.7.

Northcote and Skene (1972) established salinity classes for Australian soils using percent chloride as the criterion. All soils on the research station are classified non-saline. They have very low to low chloride (<.03%) throughout, except for Woodall where levels increase below 900 mm to a maximum .04 %.

Electrical conductivity (EC) is also used to estimate soil salinity. The EC values are very low to low (<0.45 mS m^{-1}) in all soils.

The linear regression:

$$ECm = 0.04 + 8.05 Cl (n = 150, r^2 = 0.90, P<.01)$$

where ECm is 1:5 electrical conductivity (mS m-1) and Cl is percent chloride, was calculated from the data. This differs from the theoretical relationship:

$$ECc = 6.64$$
 Cl

where ECc is the EC calculated when all anions present are chloride. The difference suggests that, although chlorides probably dominate the soluble salts, other sources of salinity are present. Shaw *et al.* (1987) use ECm, ECm/ECc and pH to set guidelines for determining the relative contribution of various sources to soil salinity. Their criteria indicate that release of cations from exchange sites due to dilution effects may contribute as well as salts other than chlorides.

8.3 Particle size analysis

The mean sand, silt and clay contents of three soil groups are compared in Figure 3. The soils are derived from alluvium and buried layers occur in every profile at varying depths below 500 mm. Nevertheless, the particle size distribution forms a consistent pattern to at least 1200 mm depth in two of the groups.

The soils of the alluvial flats and drainage depressions have uniform clay profiles with clay content gradually decreasing below 900 mm. There is a considerable silt fraction throughout though the maximum content is in the surface 300 mm. Coarse sand represents only 1-12% of the soil material. **Channel** soil has more fine sand and less clay than the other soils in the group. This is probably due to its landscape position in the deeper drainage depressions. The levee soil **Woodall** is a cracking clay with similar particle size distribution to the soils of the alluvial flats and drainage depressions. Coarse sand accounts for only 2-10% of the soil material.

• Soils of the very gently to gently undulating levees -Hodge, Callide and Callide gravelly phase

• Soils of the very gently to gently undulating levees -Woodall

• Soils of the intervening alluvial flats and drainage depressions

Figure 3 Comparative particle size analyses for three soil groups

The third group consists of the levee soils Hodge, Callide gravelly phase and Callide and is quite variable. The Callide profile is similar to the Woodall profiles but with lower clay and silt and higher fine sand fractions. Hodge and Callide gravelly phase have much less clay and silt and considerably more fine sand than all other profiles. Coarse sand has also increased, representing 8 to 28% of the surface soil and subsoil. The relative amounts of clay, fine sand and coarse sand fluctuate in their buried layers below 500 to 800 mm depth.

The differences in grade and amount of sand can be used as an aid to distinguish several soils in the field (see section 7.3). However, the relatively high silt content of some soils was not recognised while texturing field samples and ground and sieved laboratory samples. Several field textures also overestimated the clay content determined by particle size analysis, especially in **Hodge**, **Callide** and **Callide gravelly phase**. These samples generally have higher fine sand and lower silt content than those in close agreement.

8.4 Cation exchange capacity and clay activity ratio

The cation exchange capacity (CEC) of a soil indicates the potential storage of nutrient cations that are available for plant growth.

The CEC of each soil is indicated for two sampling depths in Table 9. Hodge and Callide gravelly phase have the lowest levels; Woodall, Tognolini and Melton have similar high values while Callide and Channel are intermediate.

Sanchez (1976) claims that an effective CEC of at least 4 mequiv. 100 g⁻¹ is necessary to retain most cations against leaching. The analyses for these soils can be considered as effective CEC which is the CEC determined at the field pH of the soil. The lowest value recorded to 900 mm depth was 12 mequiv. 100 g⁻¹ in **Hodge.** All soils should have the ability to retain cations against leaching.

The differences in soil CEC are a reflection of the particle size distributions evident in Figure 3. CEC is significantly (P<.01) correlated with clay content (r = .96, n = 50) and with silt (r = .82, n = 50).

The clay activity ratio is the CEC of one gram of clay (mequiv. g⁻¹ clay) and is often used as an indication of clay mineralogy. Clay activity ratios are given for two sampling depths of each soil in Table 9.

A ratio of 0.8 or higher generally indicates a dominance of smectites, the clays that shrink and swell with changing moisture status. Vermiculite also has a very high ratio but is not known as a major component of any Australian soil group (Norrish and Pickering 1983).

Hodge is the only soil on the station with ratios of 0.8 and above through the profile. The total clay content of the soil is low and shrink-swell phenomena do not occur.

The remaining soils have similar ratios, generally less than 0.75, suggesting a common clay mineralogy, not dominated by smectites. Norrish and Pickering (1983) report that some illitic clays have activity ratios approaching 0.8 and exhibit the shrink-swell phenomena usually associated with smectites. All the soils on the station have a relatively high total potassium content (see section 8.6) suggesting illites may be present.

The high CEC-clay correlation across all soils, mentioned previously, also indicates a common mineralogy.

Soil type	Sample depth	CEC	Cl ay activity ratio

	500-600	25	0.73

Table 9. Cation exchange capacity and clay activity ratio at two samplingdepths for all soils

This conclusion cannot be reconciled with field evidence for the medium to heavy clays. All profiles have analogous clay content, CEC and clay activity ratio but only three (Woodall S8, Tognolini S4 and possibly Tognolini S7) are cracking clays. Shallow (50 mm deep) cracks occurred at the Woodall S9 site and a 1 m deep pit adjacent to the Melton profile revealed no shrink-swell characteristics.

8.5 Exchangeable cations and base saturation

Levels of exchangeable calcium, magnesium, sodium and potassium are given at two depths for each soil in Table 10. Base saturation, which is the proportion of CEC occupied by these four cations (and expressed as a percentage) is also listed.

Calcium is the dominant cation throughout all soil profiles.

Consolidated Fertilisers Limited (1984) have set threshold limits for calcium and magnesium deficiency for the major crops grown in central Queensland. These are only guidelines as exchangeable calcium and magnesium levels vary widely between soils making absolute amounts unreliable as indicators of plant availability (Bruce and Rayment 1982). All the soils have levels at both the surface and at depth far in excess of any threshold values.

Exchangeable potassium levels are high to very high in all surface samples decreasing to medium-high at depth. The surface values exceed the threshold limits given for the major crops of central Queensland (Consolidated Fertilisers Limited 1984).

In Australian soils sodium is rarely deficient and often affects plant growth due to its presence in excess amounts. This aspect is discussed in section 8.7.

The exchangeable cations calcium, magnesium, sodium and potassium occupy 85 to 98% of the soil CEC in the surface soil. The soils are all base saturated at depth. Base saturation is significantly (P<.01) correlated with pH (r = .86, n = 50).

8.6 Total potassium and total phosphorus

Total potassium levels reflect the parent material, clay mineralogy and age of soils. McDonald and Baker (1977) found that, on the Emerald alluvium, total potassium decreased with increasing soil age. A similar relationship was reported for alluvial landforms at Mackay (Baker *et al.* 1985).

Profile trends of total potassium are shown for three soil groups at Biloela in Figure 4. Apart from Hodge, the soils appear to have similar clay mineralogy (see section 8.4) and, as they all occur within the same alluvial plain, probably have similar parent material. The levee soil Woodall has significantly less (P<.05) total potassium to a depth of 600 mm than the other two soil groups. This material may be older than the corresponding material in the other soils.

Buried layers are encountered between 500 mm and 1100 mm depth. Total potassium levels are not significantly different (P>.05) below 600 mm indicating these layers may be of a similar age.

		of each soil								

Figure 4 Mean total potassium profiles for three soil groups showing significant differences at the 5% and 1% levels.

Baker et al. (1985) also demonstrated an inverse relationship between total phosphorus levels and soil age. However total phosphorus is not significantly different between soil groups at any depth in these soils.

8.7 Sodicity and other indexes of soil dispersion

Several indexes have been used in Australia to indicate soil dispersion. Dispersion results in degradation of soil structure and thus decreased permeability as well as increasing susceptibility to water erosion. These indexes have been calculated for the research station soils and are presented for various depths in Table 11.

Northcote and Skene (1972) used exchangeable sodium percentage or ESP (exchangeable Na. 100/CEC) as a criterion for determining sodicity. Soil material with an ESP of 6 or more is considered sodic and likely to have some structural degradation. The **Woodall** S8 profile has sodic buried layers below 650 mm (ESP 6.2 to 6.4). All other soils are classified non-sodic.

Exchangeable magnesium, in association with sodium, has been shown to aid soil dispersion in some soils (Emerson and Bakker 1973). Clay subsoils with degraded structure but low ESP have been recorded in coastal Queensland by Teakle (1950), Thompson *et al.* (1981) and Baker *et al.* (1985). The magnesium saturation (exchangeable Mg. 100/CEC) of these materials ranged from 64 to 83 \sharp . Stace *et al.* (1968 pp185,187) also include two soils from Glenelg (Victoria) with poorly structured subsoils, low ESP and magnesium saturation in excess of 40%. Tognolini S4 is the only profile on the station with a magnesium saturation of 40% or more. This occurs below 800 mm depth.

Emerson and Bakker (1973) also used Mg:Ca ratios to assess the physical performance of some Victorian soils. They suggested that Mg:Ca ratios greater than one associated with relatively low ESP can enhance clay dispersion. All soils on the station have Mg:Ca ratios well below one.

R1 is the ratio of readily dispersible silt + clay to the silt + clay determined by particle size analysis. Baker (1977) used the index to rate soil dispersion in the Burdekin district. A ratio of <0.6 was given a low dispersion rating, 0.6 to 0.8 was considered moderate and >0.8 high. These criteria suggest that the surface sample of the **Callide gravelly phase** is the only highly dispersible material on the station. This is unusual as its ESP, magnesium saturation and Mg:Ca ratio are all quite low. In fact there was negligible correlation between R1 and the other dispersion indexes for all soils.

The ESP, magnesium saturation and Mg:Ca ratio indicate soil dispersion is not a significant factor in any of these soils. This evidence is supported by the very low to low EC values throughout all profiles (section 8.2).

Yet surface crusting is a problem on the furrow irrigated soils (Callide, Melton and Tognolini), especially when cotton is grown. This could be due to management practices, particularly the amount of cultivation, rather than any inherent soil dispersion.

Table 11. Indexes of soil dispersion for selected sampling depths in each soil

8.8 Available water capacity and predicted leaching fraction

Three methods were used to estimate the available soil water capacity (ASWC) of each soil. An ASWC was calculated from the -33 kPa and -1500 kPa water contents. The plant available water capacity (PAWC) was also determined using regression equations of Shaw and Yule (1978) based on either -1500 kPa (PAWCb) or the soil CEC (PAWCc). All three figures were converted to volumetric water using a bulk density calculated from the maximum gravimetric water content, assuming a 3% air content at that point. They were then summed to a depth of one metre. Any peaks in chloride concentrations occur below this depth suggesting water moves through all soils to at least one metre. Results are given in Table 12.

Soil	Estimato	ed availab	Predicted leaching	
	caj	pacity (mm	fraction

Table 12. Estimated available water capacity (mm) to one metre depth andpredicted leaching fraction of all soils

(a) Leaching fraction cannot be predicted for this soil

(b) Estimated available water capacity reduced in proportion to gravel content

(c) No data available

The AWSC figures are approximately double both PAWCb and PAWCc values. The ASWC calculation relies on -33 kPa being an accurate estimate of the soil upper storage limit but the estimate has been found unreliable on ground and sieved samples (Thorburn and Gardner, in press). The ASWC figures probably overestimate the actual available water capacity of the soils.

The PAWCb and PAWCc estimates are similar and are comparable to values reported by Williams (1983) for equivalent field textures in a range of Australian soils. The coarser textured soils, Hodge and Callide gravelly phase, have lower available water capacity than the finer textured soils. Callide appears to be intermediate between these two groups. The gravel content of Callide gravelly phase can range between 10 and 50% and its PAWC can vary accordingly.

Deep drainage is an important characteristic of irrigated soil as it is a major factor determining whether soluble salts will accumulate in the root zone. One method of assessing deep drainage of a soil is to estimate its leaching fraction, which can be expressed as the ratio of the salinity of output water (or soil salinity at depth) to the salinity of input water. A model described by Shaw *et al.* (1987) was used to predict a leaching fraction for soils on the station. The ratios are given in Table 12. There are no algorithms available in the model to predict a leaching fraction for soils such as **Hodge**. The model overestimates the value for **Channel** as the ratio should not exceed unity but, nevertheless, indicates this soil has a high leaching fraction. **Callide gravelly phase** has the second highest ratio, **Woodall** and **Melton** have the lowest ratios while **Callide** and **Tognolini** are intermediate.

Hansen and Thorburn (1987) have related the leaching fraction to the relative concentration of soil salinity compared with the salinity of input water. Soils with a ratio below approximately 0.2 have a propensity to accumulate soluble salts. Melton and Woodall fall within this category and Callide and Tognolini are marginal.

8.9 Plant nutrients in surface soil

The general fertility ratings of Bruce and Rayment (1982) are given for the soil bulk surface samples in Table 13. Urea was the only fertiliser used on the station prior to sampling except for scattered applications of zinc. The **Tognolini** S4 profile received a dressing of 10 kg Zn ha⁻¹ six months before sampling.

Bicarbonate extractable phosphorus levels are high to very high on all soils regardless of cropping history. The coarser textured soils Hodge and Callide gravelly phase vary from 53 to 80 mg kg-1 P while the others range from 120 to 190 mg kg-1 P. Acid extractable phosphorus levels are all very high (180 to 470 mg kg-1 P).

The extractable potassium levels are a reflection of the high to very high exchangeable levels listed in Table 10.

Zinc levels are rated as medium for all soils except **Melton** which is very high. There are no records of zinc being applied to this site. Further sampling of this soil is warranted. The application of zinc at S4 profile prior to sampling has not resulted in a high value.

Consolidated Fertilisers Limited (1984) have set threshold values as guidelines for assessing zinc deficiency in both acid and alkaline soils for the major crops grown in central Queensland. Three of the ten profiles (S2, S5 and S8) approximate these limits.

Copper levels are medium in all soils; manganese levels are medium to high. A deficiency of either element is unlikely.

The organic carbon levels are mainly low to medium. **Channel** is the only soil with a high value. The range in values is similar for both cropped and pasture sites. Total nitrogen levels are low to very low. Application of urea does not appear to be increasing the soil nitrogen reserves.

Soil type	Extract	able phosphorus	· · · · · · · · · · · · · · · · · · ·	Extractable				Total nitrogen
	Acid	Bicarbonate	Potassium	Copper	Zine	Manganese		-
Hodge	very hig	h high	very high	medium	medium	medium	low	low
Callide gravelly phase	very hig	h high	very high	medium	medium	medium	low	low
Callide	very hig	h very high	very high	medium	medium	medium	low	low
Woodall	very hig	h very high	very high	medium	medium	medium -high	medi um	low
Melton	very hig	h very high	very high	medium	very high	medium	medium	low
Tognol ini	very hig	h very high	high- very high	medium	medium	high	low- medium	low- very low
Channel	very hig	h very high	very high	medium	medium	high	high	low

9. IMPLICATIONS FOR FIELD TRIALS

9.1 Soil type homogeneity

The surface fertility of all soils is similar (Table 11). Soil CEC values are all above the minimum considered necessary to retain nutrients against leaching. The levels of exchangeable calcium, magnesium and potassium are also adequate in every soil. All soils can be considered homogeneous with respect to nutrient fertility.

The soil physical characteristics are more variable. Particle size analysis reveals two distinct groups. Subsoil structure varies from massive (in Hodge) to weak prismatic (Callide) and moderate lenticular in Woodall. Field evidence suggests the finer textured soils can be split into self-mulching, cracking clays (Woodall and Tognolini) and noncracking clays with a surface crust (Channel and Melton).

These differences are reflected to some extent in the PAWC estimates. Three soil groups can be delineated on the basis of their relative soil PAWC:

- . Low Hodge, Callide gravelly phase
- . Intermediate Callide
- . High Woodall, Channel, Tognolini, Melton

The PAWC of Callide gravelly phase can vary widely depending upon gravel content.

Three different soil groups are obtained when considering deep drainage characteristics. The predicted leaching fractions of **Melton** and **Woodall** indicate these soils have potential to concentrate soluble salts from irrigation water. **Callide** and **Tognolini** have marginally higher leaching fractions and may have some potential as well. **Channel, Callide** gravelly phase (and probably Hodge) have much higher values suggesting their potential is minimal.

9.2 Conclusions

As the soils have similar nutrient status, PAWC will be the major soil factor influencing yield variability under rainfed conditions. With irrigation, the principal effect of soil PAWC will probably be to determine frequency of watering rather than total volume applied or plant yields.

Further research is warranted to estimate more accurately soil PAWC and to check whether the differences are of practical or economic significance.

During the interim it is advisable to design rainfed trials so that each replicate is wholly within the three PAWC groups identified. Moreover, it is recommended that **Callide gravelly phase** not be used at all as its PAWC will vary widely with gravel content. The shallow drainage depressions contain **Tognolini** soil and are runon areas which may receive more water than other areas during high rainfall. It would be unwise to include these depressions in any trial area.

Channel occurs in deep drainage depressions which are probably former overflow or main channels of Callide Creek. Such run-on areas do not represent a significant portion of central Queensland and this soil could be excluded from crop trials.

Tognolini also occurs in a level back-plain through blocks P1 to P4 and Q1 to Q4. This run-on area is large enough to accommodate a full replicate for most trials.

The accompanying soils map can be used to locate trials. However it must be remembered that apart from **Woodall** and **Channel**, the mapping units are not pure; that is, they contain more than one soil. The soils that may occur in each mapping unit are listed in Table 7. The greatest soil complexity is in the units containing **Callide gravelly phase** which could not be mapped separately. This problem can be avoided by not designing trials in blocks V2, W1, W2, W3, Y and Z.

With long-term irrigation it is probable that Woodall and Melton will accumulate soluble salts from the input water. It is also possible that Callide and Tognolini will accumulate salts. Further investigation of this potential hazard is recommended.

10. ACKNOWLEDGEMENTS

I wish to thank Mr Peter Thorburn for his willing advice in interpreting the soil salinity, available water and leaching fraction data and Mr Gary Blight for advising on statistical analyses of the laboratory data.

I am also indebted to Mr Alan McTaggart for providing background information and to the station farmhands for their assistance during field work.

Mr Dennis Baker supervised the laboratory analyses and assisted with interpretation of results.

Mr Brian Slater and Mr Ed Turner provided valuable comments and advice on the report.

Officers of drafting section of Land Resources Branch prepared the map, figures and diagrams included in this report.

APPENDIX I

Conventions used in describing and classifying the soil types

PPF (Principal Profile Form)

As in Northcote (1979).

рĦ

Based on field determinations in A1 or Ap horizon and at 300, 600, 900, 1200 and 1500 mm.

Description

The terminology of McDonald *et al.* (1984) is used to describe the most common range of profile features encountered in the soil type, except for colour. The summary description, for example <u>Black earth and dark non-</u> <u>cracking clay</u>, is from either Stace *et al.* (1968) if the soil fits a great soil group, otherwise from Northcote *et al.* (1975).

Colours

Colour codes are those of Oyama and Takehara (1967) for moist soil while colour nomenclature is that of McDonald (personal communication), which is based on the Value/Chroma rating system of Northcote (1979) and utilises the following table:

Value/Chroma 2a = 4/1 - 4/2 to 6/1 - 6/2Value/Chroma 2b = 5/3 - 5/4 to 6/3 - 6/4

Value/ Chroma	1	2a	2b	4	5
Hue					
5 Y	dark	grey	yellow-grey	yellow	olive
2.5 Y	dark	grey	yellow-grey	yellow	olive-
brown					
10 YR	da rk	grey	yellow-brown	yellow	brown
7.5 YR	dark	grey-brown	brown	yellow	brown
5 YR	dark	grey-brown	brown	red-brown	red-brown
2.5 YR	dark	grey-brown	red-brown	red	red
10 R	dark	red-grey	red-brown	red	red

SOIL TYPE Melton SITE NO SIO A.M G. REFERENCE: 247 680 mE 7 301 300 mN ZONE 56

GREAT SOIL GROUP: No suitable group PRINCIPAL PROFILE FORM: Uf6 32P SOIL TAXONOMY UNIT Ustollic Haplargid FAO UNESCO UNIT: Luvic Xerosol

SUBSTRATE MATERIAL Unconsolidated substrate materials CONFIDENCE SUBSTRATE IS PARENT MATERIAL: Almost certain or certain

SLOPE 0 % LANDFORM ELEMENT TYPE Plain LANDFORM PATTERN TYPE Level plain

VEGETATION STRUCTURAL FORM: DOMINANT SPECIES

#### ANNUAL RAINFALL · 699 mm

#### PROFILE MORPHOLOGY:

CONDITION OF SURFACE SOIL WHEN DRY: Surface crust

TYPE OF MICRORELIEF No microrelief SURFACE COARSE FRAGMENTS No coarse fragments

HORIZON	DEPTH	DESCRIPTION
Ар	0 to 10 m	Dark reddish brown (5YR3/2) moist, greyish brown (5YR4/2) dry, no mottles, medium clay, no coarse fragments, dry moderately strong, no segregations. Gradual to-
B21	.10 to 75 m	Brownish black (5YR3/1) moist, no mottles, heavy clay, no coarse fragments, moderately moist very firm, no segregations slightly calcareous. Gradual to-
D1	.75 to 1 30 m	Brown (7 5YR4/6) moist, brownish black (7 5YR3/1) moist; no mottles; fine sandy medium clay, no coarse fragments, moderately moist very firm, very few fine carbonate soft segregations. Gradual to-
D2	1.30 to 1 50 m	Dark brown (7 SYR3/3) moist, black (7.5YR2/1) moist; no mottles, fine sandy medium clay, few small pebbles, subrounded unspecified coarse fragments, moderately moist moderately firm, no segregations slightly calcareous
